Abstract

Riga’s papilloma or Cardarelli’s aphae describes ulceration on the ventral of the tongue in neonates and infants. It is often associated with natal or neonatal teeth. It may rarely occur in older infants. Failure to diagnose and properly treat this lesion can result in inadequate nutrient intake for the infant.

Treatment should begin conservatively and should focus on eliminating the source of trauma. The purpose of this study is to describe a clinical case of an infant with Riga's papilloma on the ventral of the tongue along with the clinical management. The case is very interesting and can be very useful to Pediatric Dentists. A 3 month-old male infant reported for evaluation of a neonatal tooth that was erupting in the mandibular anterior region together with a non-healing oral ulcer. The tooth was not present at the time of his birth.

Intra Oral examination revealed one firm tooth crown in the mandibular anterior central incisor region. Examination also revealed ulceration on the ventral surface of tongue. As the neonatal tooth was the cause of the ulceration and pain, extraction of the tooth was chosen as treatment of choice. Patient was re-examined after 3 weeks. Examination revealed complete healing of the ulcer and the extraction socket.

With subsequent patient follow-up (at 7 months of age), an occlusal radiograph revealed erupting mandibular central incisors. Hence it was possible to conclude that the neonatal tooth had been a supernumerary.

Keywords: Riga’s papilloma, Cardarelli’s aphae, natal and neonatal teeth, traumatic ulcer.

Introduction

‘Riga’s papilloma’ is a rare, benign traumatic ulceration on the ventral surface of the tongue in neonates and infants typically between 1 week and 1 year of age.1,2 It is frequently associated with natal, neonatal, or primary lower incisor teeth.3 The lesion was first described by Antonio Riga, an Italian physician, in 1881.4

Histologic studies and additional cases were subsequently published by F. Fede in 1890. It has been subsequently known as ‘Riga's boil’ or ‘Riga’s disease’.5

Typically, the benign lesion begins as an ulcerated area on the ventral surface of the tongue exposed to repeated trauma from a natal or neonatal tooth.2 With repeated trauma, it may progress to an enlarged fibrous mass and resemble a traumatic ulcerative granuloma (with stromal eosinophilia). Often, the lesion develops a rolled white hyperkeratotic border immediately adjacent to the ulceration. Occasionally, the underlying proliferative granulation tissue results in a raised exophytic lesion similar to a pyogenic granuloma.6

The clinical presentation many resemble squamous cell carcinoma causing concern but are not frequently reported.7,8

It may interfere with proper suckling and feeding and the pain associated with the lesion may put the neonate at risk for dehydration and failure to thrive. In such instances, dental intervention may be required. Treatment should begin conservatively and should focus on eliminating the source of trauma. The purpose of this study was to describe a clinical case of an infant with Riga’s papilloma on the ventral of the tongue.

Case Report

A 3 month-old male infant was referred to the out-patient department, Department of Pedodontics, Sardar Patel Postgraduate Institute of Dental & Medical Sciences by his attending paediatrician for evaluation of a neonatal tooth that was erupting in the mandibular anterior region together with a non-healing oral ulcer of approximately 1 month duration. The tooth was not present at the time of his birth. The mother complained of child exhibiting inadequate nutrient intake together with pain during suckling.

A review of his medical chart revealed that he had a birth weight of 1,665 g. Maternal and paternal medical and social histories had no evidence of heredity influence or other significant information.

Intra Oral examination revealed one firm tooth crown, whitish in colour in the mandibular anterior central incisor region (Figure 1). Examination also revealed 6 mm x 11 mm ulceration on the ventral surface of tongue that extended from anterior border of the tongue to lingual frenum (Figure 2). On palpation, area elicited a pain response from the patient.

Examination of the rest of intraoral mucosa revealed no other lesions. Difficulty in obtaining a radiograph of the region, due to the child’s age, prevented immediate confirmation of whether the tooth in question belonged to the normal series or was a supernumery.

Based on clinical findings, diagnosis of ‘Riga’s Papilloma’ was made. As the neonatal tooth was the suspected cause of the ulceration and pain, extraction of the tooth was chosen as treatment of choice. Extraction was carried out under topical local anaesthesia, which the infant tolerated well (Figure 3).

Clinical examination of the extracted tooth revealed pulp tissue (Figure 4) which was sent for histological examination. Histological results revealed it to be normal, underdeveloped pulp tissue with sparse innervations and cellular components.

Figure 1. Intra Oral Photograph of 3 month old infant showing Neonatal Tooth in mandibular anterior region.

Figure 2. Intra Oral Photograph showing ‘Riga’s papilloma’ on the ventral surface of the tongue.

Figure 3. After Extraction of Neonatal Tooth.

Figure 4. Histological Photograph of extracted tooth showing normal, underdeveloped pulp tissue.
Histological examination of the neonatal tooth showed a thin layer of hypoplastic enamel, atubular dentin and no evidence of root formation (Figure 5).

Patient was re-examined after 3 weeks. Examination revealed complete healing of the ulcer and the extraction socket (Figure 6).

The baby appeared to be much more content and the mother reported that her baby was feeding normally and gained weight. With subsequent patient follow-up (at 7 months of age), an occlusal radiograph revealed erupting mandibular central incisors.

Hence it was possible to confirm that the neonatal tooth had been a supernumerary (Figure 7).

Infants born with teeth or teeth erupting immediately after birth have appeared in the medical and dental literature. These teeth have been referred to as 'Natal teeth', 'congenital teeth', fetal teeth, and predecidual teeth. If the primary teeth erupt during the third to the fifth month of life, they are termed precocious dentition.

According to Massler and Savara, natal teeth indicate teeth present in oral cavity at birth and 'neonatal teeth' are those which erupt during the neonatal period i.e., from birth to thirtieth day of life.

Natal and neonatal teeth are rare in the buccal cavity. Their incidence has been investigated in many studies. In a 1995 review article, Zhu and
Simple chronic traumatic ulcerations occur most often on the tongue, lips, and buccal mucosa (sites usually injured by the dentition). The presence of natal or neonatal teeth may lead to formation of a traumatic ulcer on the ventral surface of the tongue, which is known as Riga’s Boil or Riga’s aphthae. Although usually associated with natal or neonatal teeth, it may also occur in older infants after the eruption of the primary lower incisors.

Various terms have been applied to this lesion, including Cardarelli’s aphthae, Cardarelli’s disease, Fede’s disease, Riga’s aphthae, Riga’s boil, Riga’s papilloma, Riga’s disease, Riga-Fede’s disease, sublingual ulcer, sublingual granuloma.

This lesion was of particular concern in Italy in the late 1800s because it was frequently associated with malnourished infants and often resulted in death. In some cases, it was also thought to be diagnostic of whooping cough. Hence it was considered that the lesion was of traumatic origin.

Buchanan & Elzay reported these lesions to be found on the anterior ventral surface of the tongue. In our present case the ulceration extended from anterior border of the tongue to lingual frenum. According to Slayton, the dorsal surface may also be affected. Ventral tongue lesions contact the mandibular anterior incisors whereas dorsal lesions contact the maxillary incisors. Zangenlein & others reported cases on the buccal mucosa, palate, and lip, but the tongue remains to be the most common site of involvement.

Feeding behaviours also contribute to the trauma that causes this type of lesion. Hence, parents are advised to modify their feeding methods to try to avoid the child positioning his tongue over the teeth and to minimize the amount of sucking needed to obtain fluids. This may involve using a bottle with a larger hole in the nipple or a Sippy cup that requires less vigorous sucking. According to Jariwala, the parent can also attempt feeding by spoon to minimize trauma to the tongue.

Treatment should begin conservatively and should focus on eliminating the source of trauma. For traumatic ulcerations that have an obvious source of injury, the irritating cause should be removed first. Jariwala et al. suggested biopsy for lesions that remain for 2 weeks after removal of the cause. Ahmet et al. reported a patient with a traumatic ulceration extending from the anterior border of the tongue to lingual frenum.
reported a rare recurrence rate. In case of mild to moderate irritation to the tongue, conservative treatment such as smoothing the incisal edge with an abrasive instrument is advocated\textsuperscript{11,14}. Alternatively, a small increment of composite may be bonded to the incisal edges of the teeth\textsuperscript{13}.

In this case, ulcerated area was large and denuded and even a reduced incisal edge may still contact and traumatize the tongue during suckling, enough to delay healing. Extraction of the natal or neonatal tooth, like in this case was recommended. Tooth extraction had resolved the ulceration too. Although reported by Rutt\textsuperscript{12}, the possibility of pyogenic granuloma in the tooth extraction place, we did not observe this kind of alteration in our present case.

Conclusions

Our male infant presented a single neonatal tooth in the mandibular central incisor region with hypoplastic enamel. The paediatricians’ concern over the infant’s failure to gain weight due to ulceration’s interference with suckling dictated the need for rapid resolution of the lesion.

So extraction of the natal tooth was chosen over more conservative treatments. With subsequent patient follow-up, an occlusal radiograph revealed erupting mandibular central incisors. Hence it was possible to confirm that the neonatal tooth had been a supernumerary.
